Abstract
Cancer and its treatments produce a myriad of burdensome side effects and significantly impair quality of life (QoL). Exercise reduces side effects and improves QoL for cancer patients during treatment and recovery. Exercise prior to, during, and after completion of cancer treatments provides numerous beneficial outcomes. It represents an effective therapeutic intervention for preparing patients to successfully complete treatments, for reducing acute, chronic, and late side effects, and for improving QoL during and after treatments. This overview of exercise oncology and side effect management summarizes existing evidence-based exercise guidelines for cancer patients and survivors.

Keywords
Exercise, physical activity, cancer, side effects, quality of life, yoga, tai chi, aerobic exercise, resistance exercise, cancer-related fatigue, bone loss, muscle loss, mental health, cardiotoxicity

Over 1.6 million Americans will be diagnosed with cancer in 2012, adding to the approximately 12 million Americans already living with a diagnosis of cancer.1 The vast majority of these cancer patients are receiving or have completed treatment for their disease. The overall survival rate for all types of cancer has increased from less than 50% in 1975 to over 68% in 2012.1 Therefore, many Americans with a wide variety of cancers are living beyond the historical 5-year survival marker. The number of cancer survivors will continue to increase with continued improvements in screening and treatment. Despite these improvements, however, many cancer survivors suffer from the acute, chronic, and late side effects of treatment. Acute side effects are those which develop during treatment and last a short time (days, weeks, or months); chronic side effects develop during treatment and persist for months to years, and late side effects arise months or even years after treatments are complete. All of these side effects negatively impact cancer patients and survivors during, immediately following, and long after treatments. Exercise is an effective therapeutic intervention for preparing patients to successfully complete treatments, managing acute, chronic, and late side effects and improving quality of life (QoL).

Side Effects Of Cancer Treatment
Treatments for cancer often include surgery, chemotherapy, radiation therapy, hormone therapy and/or a combination of these modalities. These treatments lead to a myriad of physical and psychological side effects which subsequently interfere with a cancer patient’s ability to complete treatments as prescribed, function independently, perform activities of daily living, and live with a high QoL. Side effects are especially burdensome in older adults who are at greatest risk for functional impairment after cancer treatment. Among the most onerous side effects stemming from cancer and its treatments are cancer-related fatigue (CRF), cognitive impairment, sleep problems, depression, pain, anxiety, and physical dysfunction including impaired muscular function, reduced cardiopulmonary function, and decreased bone mineral density.

Cancer-related Fatigue
Cancer Related Fatigue (CRF) is defined as “a distressing, persistent, subjective sense of physical, emotional and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent physical activity and interferes with usual functioning.”2 CRF is differentiated from other types of fatigue by the timeline in which it occurs (i.e., after a cancer diagnosis or treatment), its severity and persistence, the inability to alleviate it through rest, and its negative impact on function and overall QoL.3 CRF is the most common symptom experienced by patients and survivors.4–6 Patients report CRF from the time of diagnosis through treatment completion and often during the months or years after treatments are complete.5–7,10,23 Nearly all cancer patients who are undergoing treatment report CRF, and almost half
Supportive Oncology

report their CRF as severe.2,3,24 CRF is a chronic problem in over two-thirds of cancer survivors, and nearly 40 % describe it as severe for at least six months following treatment.2,3,24 CRF is more common, more severe, and persistent in patients who receive more than one type of treatment.2,3,24 CRF is a dose-limiting toxicity resulting from established therapies and from newer targeted agents (such as tyrosine kinase inhibitors), ultimately limiting their effective use alone and in combination with other agents.3,23 CRF is associated with a variety of co-morbidities, such as sleep problems, depression, pain, medication side effects, nutritional imbalance, and physical inactivity.2,3,23 CRF is often described by patients as the most distressing side effect of treatment, even more so than nausea, vomiting, sleep problems, pain, and depression, due to its impact on their ability to perform activities of daily living and QOL.5–7,22

Cognitive Problems
Cognitive impairments (e.g., problems with memory, attention, and executive function), for which there is no treatment, are a clinically significant problem for up to 75 % of breast cancer patients during chemotherapy and persist in 20-35 % of survivors during the years following treatment.30–32 Patients receiving chemotherapy have much greater difficulty with cognitive function than patients receiving radiation treatments.21 These cognitive problems can have a severe negative effect on the mental and physical well-being of patients and impair function (e.g., activities of daily living) and QOL. For example, one study found that 57 % of women with breast cancer were unable to do their jobs as effectively, unable to maintain the same job, or unable to work at all following chemotherapy due to difficulty with memory, maintaining attention, and accomplishing tasks requiring executive function.29,34

Sleep Problems, Depression, Pain, and Anxiety
Between 30 and 50 % of cancer patients report sleep disruption.35,36 Poor sleep quality is common among cancer patients and survivors; it is several times more prevalent than in the general population.35,36 Patients and survivors who spend a significant amount of time napping report increased sleep problems.21 Additionally, 10–25 % of cancer patients report depression.20 Pain is also common; 45–59 % of cancer patients and survivors report pain.20 Anxiety is reported by approximately half of cancer patients and survivors; 20 % meet the clinical criteria for an anxiety disorder.20

Physical Dysfunction
Cancer and its treatments can lead to impaired muscle function through atrophy and loss of strength.30,32,33 Reduced muscle mass and strength impair a cancer patient’s ability to perform activities of daily living and remain independent during and following treatment, which is of particular concern among older patients.30,33 Chemotherapy and radiation treatments may also lead to cardiac and pulmonary dysfunction.33,34 Patients treated with anthracyclines, taxanes and/or trastuzumab may develop acute or chronic cardiac dysfunction and, in some cases, the maximum cumulative dose for these agents is limited due to potential cardiomyopathy.33,34,35 Cardiotoxicities can develop during treatment or become manifest years after treatment completion.38 Radiation to the chest increases the risk of cardiac damage.39 Patients treated with methotrexate and bleomycin may develop pulmonary toxicities.39,40 Patients treated with chemotherapy, oophorectomy, and aromatase inhibitors often decrease production of endogenous estrogens and develop premature menopause leading to reduced bone mineral density and an increased risk of fracture.40,41

Aging
Older adults are at a greater risk of developing cancer than those who are younger. In the US, approximately 60 % of new cancer diagnoses occur in those who are 65 years of age or older.23 Compared to older adults without a history of cancer, older cancer survivors suffer from a greater incidence of frailty and more limitations in activities of daily living, lower self-rated health, reduced QOL, and a greater prevalence of geriatric syndromes, such as dementia, depression, falls, incontinence, and osteoporosis.33,34,35

Exercise For Side Effect Management
The selection of cancer treatments is based on numerous factors including the type and stage of cancer and the patient’s underlying health status.45 The type of cancer, types of treatments, and underlying health status of the cancer patient and survivor influence the development, type, and severity of side effects.39,45 Exercise is an effective intervention for improving side effects, such as CRF, cognitive impairment, sleep problems, depression, pain, anxiety, and physical dysfunction, including impaired muscular function, cardiopulmonary function, and bone density. Exercise can be individually tailored to the specific needs of each cancer patient or survivor.4,2,12,20–22 Exercise is an effective behavioral intervention with the potential to mitigate multiple side effects and improve physical function in older cancer patients and survivors as well.16,17

Aerobic Exercise During and Following Treatment
Aerobic exercise utilizes large muscle groups for prolonged periods of time.16 Examples of aerobic exercises include walking, running, cycling, and swimming.16 Aerobic exercise is an effective intervention for CRF, sleep disruption, depression, anxiety, cardiopulmonary function and QOL among cancer patients and survivors.4,45,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100

Aerobic exercise is beneficial when performed by cancer patients who are undergoing treatment. Mock and colleagues reported that home-based walking at a moderate intensity (50–70 % of maximum heart rate), performed for 10 to 45 minutes per day, four to six days per week, for one to six months, during chemotherapy and radiation treatment for breast cancer reduced CRF, sleep disruption, depression, and anxiety while improving cardiopulmonary function and QOL.45,48,62 Another study in female breast cancer patients who were undergoing chemotherapy concurrent with participation in a progressive aerobic exercise intervention showed improvements in anxiety. The exercise intervention began with three sessions per week, 15 minutes per session at 60 % of VO2 peak and progressed to 45-minute sessions at 80 % of VO2 peak. The patients used a treadmill, cycle ergometer, or elliptical trainer.16

Prostate cancer patients undergoing radiation treatments while participating in a moderate intensity (60–70 % maximum heart rate) home-based walking program for 30 minutes a day, three days a week for 10 weeks reported improvements in CRF and cardiopulmonary function compared to usual care controls.16 Colorectal cancer patients who received chemotherapy and engaged in a moderate intensity walking (65–75 % maximum heart rate) and flexibility program for 20 to 30 minutes per day, three to five days per week showed improvements
in CRF, depression, anxiety and cardiopulmonary function. They also reported greater functional, physical, and emotional well-being and higher QOL than controls.64 Aerobic exercise has also been shown to improve sleep quality in cancer patients and survivors. Breast cancer survivors receiving hormonal treatment who engaged in a home-based moderate-intensity walking intervention four times per week, 20 minutes per day reported improved sleep quality.68

Dimeo and colleagues assessed the benefits of a cycle ergometer exercise intervention in cancer patients who had undergone surgery for lung or gastrointestinal tumors. Patients were prescribed a stationary cycle intervention for 30 minutes per day, five days per week, for three weeks and reported improvements in CRF, physical performance, and global health.71 Dimeo and colleagues performed another cycle ergometer exercise intervention in cancer patients who were receiving high-dose chemotherapy followed by autologous peripheral blood stem cell transplantation. The intervention consisted of a moderately intense bed cycle ergometer interval program. Patients performed one minute intervals at 50% of heart rate reserve followed by one minute of rest, for a total of 30 minutes, seven days per week. Patients who exercised reported less CRF and psychological stress than usual care controls.71

Aerobic exercise also has beneficial effects following treatment. Breast cancer survivors who had completed treatment were given a moderate intensity cycle ergometer intervention, three times per week for 15 weeks. Sessions were 15 minutes in duration during weeks one through three and progressed to 35 minutes by weeks 13 through 15. Participants in the exercise group showed significant improvements in cardiopulmonary function and QOL.83

Resistance Exercise During and Following Treatment
Resistance exercise involves muscle contraction against resistance and leads to improvements in muscular function and bone density.96 Resistance can be achieved by using hand-held dumbbells, resistance bands, or even body weight.106 Resistance training is safe, reduces side effects, and improves QOL when performed during and following cancer treatment.43,96,106,112

During chemotherapy for breast cancer, resistance training, consisting of two sets of eight to 12 repetitions, three times per week for the duration of chemotherapy, resulted in an increase in upper and lower body strength and lean body mass when compared to a usual care control group.12 Courneya and colleagues also found that breast cancer patients undergoing chemotherapy were able to tolerate higher relative doses of chemotherapy if engaging in resistance exercise.55

Resistance training is safe and efficacious for breast cancer survivors who have recently completed primary treatment. Schmitz and colleagues implemented a twice weekly resistance training intervention lasting six to 12 months. The intervention was safe and resulted in decreased body fat and increased lean body mass.69 Ahmed and colleagues also assessed the safety of resistance training in breast cancer survivors who had recently completed treatment. Twice-weekly resistance training, lasting for six months, did not result in any change in arm circumference in participants and therefore did not seem to contribute to the development of lymphedema.64 Breast cancer survivors who performed moderate intensity resistance training in addition to jump/impact training three times per week for one year benefited from a reduction in fracture risk due to preservation of bone mineral density at the lumbar spine in comparison to a control group. This preservation may be particularly beneficial for breast cancer survivors taking aromatase inhibitors.113 A progressive, moderate intensity resistance and impact training intervention, including jumping exercises, preformed three times per week for one year was found to preserve bone mineral density in the lumbar spine in breast cancer survivors on aromatase inhibitors. Resistance training performed three days per week for 12 weeks by prostate cancer survivors receiving androgen deprivation therapy resulted in improved CRF, cognitive function, QOL, and muscular strength.12

Combined Aerobic and Resistance Exercise
Researchers have also assessed the benefits of exercise programs that combine aerobic and resistance exercise on cancer- and treatment-related side effects. Mustian and colleagues showed the combination of aerobic and resistance exercise as part of an individually tailored, four-week intervention for breast and prostate cancer patients improved CRF, QOL, sleep quality, aerobic capacity, strength and immune function.96,97 Associations between interleukin-6 levels and sleep efficiency and duration suggested that improvements in sleep due to exercise may be mediated by cytokines.98 In addition, participants were able to progressively increase the number of steps walked per day from 5,000 to nearly 12,000 despite undergoing radiation treatments.96,106,112

A combined aerobic and resistance training intervention performed two days per week for 12 weeks resulted in improved muscle mass, muscular strength, and physical function among prostate cancer survivors undergoing androgen suppression therapy.55 Milne and colleagues tested an exercise intervention that combined aerobic and resistance training for 12 weeks and found improved muscular strength and cardiopulmonary function in breast cancer survivors.82 A four-week combined aerobic and resistance exercise intervention in older prostate cancer patients undergoing radiation treatments resulted in improvements in CRF, cardiopulmonary function, and strength.112 A phone-based intervention aimed at increasing exercise and improving diet over the course of six months showed promise for improving physical functioning in older cancer patients.113 Unfortunately, very little research has focused on using exercise interventions in older cancer patients or survivors.114

Mindfulness-based Exercise
Tai Chi Chuan and yoga are mindfulness-based exercise interventions that provide substantial benefits for cancer patients by relieving side effects, improving physical function, and increasing QOL. Mustian and colleagues demonstrated that a community-based, 12-week, 15-move, Yang-style short-form of Tai Chi Chuan improved muscular function, cardiopulmonary function, body composition, QOL, bone metabolism, and immune function among breast cancer survivors.115-119 One very recent, non-controlled, feasibility study showed a positive effect of 10 weeks of Tai Chi Chuan (two times/week, 60 minutes/session) on memory, attention, and executive function in cancer survivors, suggesting that exercise may be a promising intervention for cognitive function in this population.120

Joseph and colleagues reported improvements in sleep, QOL, treatment tolerance, and mood, among patients participating in yoga while receiving radiation treatments.110 The intervention consisted of a 90-minute session,

Advises
- Ask about the frequency, intensity, duration, and mode of exercise
- Review the benefits of exercise
- Review the ACSM Exercise Guidelines for Cancer Survivors

Assess
- Assess exercise limitations and contraindications
  - Cancer-specific
  - Cardiovascular
  - Pulmonary
  - Metabolic
  - Orthopedic
  - Other (e.g., neuromuscular)
- Assess exercise risk level
  - Low
  - Moderate
  - High

Assist
- Assist with identifying exercise barriers and ways to overcome them:
  - Assist with setting appropriate exercise goals
  - Assess with identifying exercise limitations and contraindications and management
  - Assist with identifying exercise risk and management
    - If low risk:
      - Encourage to begin or continue exercise
      - Encourage striving to reach ACSM recommendations
      - Refer to exercise oncology professional if patient desires
    - If moderate risk:
      - Refer to exercise oncology professional
      - Encourage to begin or continue exercise
      - Encourage striving to reach ACSM recommendations
    - If high risk:
      - Refer to medical professional for limitations and contraindications
      - Assist with setting appropriate exercise goals
      - Assist with identifying exercise limitations and contraindications
      - Encourage to begin or continue exercise
      - Encourage striving to reach ACSM recommendations

Advise
- Review the benefits of exercise
- Review the ACSM Exercise Guidelines for Cancer Survivors

ACSM exercise risk
- Low risk if:
  - No cancer-specific concerns
- Moderate risk if:
  - ≥1 risk factors for cardiovascular complications with exercise
  - No diagnosis or signs and symptoms of active cardiovascular, pulmonary, metabolic, orthopedic or neuromuscular disease

Considerations and Contraindications for Exercise

Oncologists should discuss with cancer patients and survivors how they can safely begin or continue an exercise program during and after treatments. Patients must also be informed of any potential contraindications (e.g., orthopedic, cardiopulmonary, oncologic) that might affect their exercise safety and tolerance. Contraindications do not necessarily mean that a cancer patient or survivor cannot exercise at all; in fact, this is rarely the case. In most instances, contraindications simply require specific modifications to the exercise regimen so that the individual can exercise safely and still achieve physical and mental health benefits (see Table 1). Many cancer patients will be able to safely initiate or continue an exercise program with the goal of achieving the levels of exercise, both aerobic and resistance, recommended by the American College of Sports Medicine (ACSM) for cancer patients and survivors.

Active exercisers or those at low to moderate risk, based on the ACSM guidelines, are not required to obtain medical clearance to continue or begin a low to moderate exercise program (see Figure 1). However, a medical assessment by qualified medical professionals (e.g., oncologist, surgeon, cardiologist, orthopedist, physical therapist) along with appropriate management of cancer-specific, cardiovascular, pulmonary, metabolic, orthopedic or other co-morbid conditions, is advisable for two times per week, for eight weeks. Yoga postures, breathing, and visualization exercises were used. Cohen and colleagues found less sleep disturbance among lymphoma patients participating in Tibetan yoga once per week for seven weeks. Patients were receiving treatment or within 12 months following completion of treatment. The Tibetan yoga intervention consisted of one yoga session a week for seven weeks, focusing on yoga postures, visualization, breathing, and mindfulness.

Providing Information

The majority of cancer patients report that they do not discuss initiating or continuing an exercise program with their treating oncologist or primary care physician throughout their cancer experience. Yet, research shows that cancer patients want their oncologists to initiate discussions about exercise. Cancer patients would prefer to receive information shows that cancer patients want their oncologists to initiate discussions about exercise.124 They prefer receiving this information shortly after they have initiated (i.e., during chemotherapy and during radiation therapy); specifically, they prefer receiving this information shortly after they have initiated treatments and prior to completion. Given the benefits of exercise during cancer treatments, oncologists should routinely discuss exercise and physical activity with their patients. The information below, in Figure 1, and in Tables 1 and 2 can help guide these discussions.
Exercise Recommendations for Cancer-Related Side Effects—A Review

</table>

Individuals at moderate risk wanting to participate in vigorous exercise and those at high risk initiating low to moderate intensity exercise, based on the ACSM guidelines. Cancer survivors should be evaluated for musculoskeletal morbidities, peripheral neuropathies, and fractures, if they have received or are currently on hormonal treatments. Cancer patients with additional concerns, such as bone metastasis and cardiac toxicity, should be assessed to determine if and how they can safely exercise. Medical evaluations should be conducted prior to the initiation of exercise testing, prescription and participation. It is strongly suggested that exercise testing, prescription and monitoring be done by qualified exercise professionals, as described in the next section, for all cancer patients and survivors, but, particularly, for individuals at moderate risk beginning or continuing vigorous exercise and those at high risk commencing or continuing any level of exercise. In all cases, the exercise prescription should be developed to target relevant cancer- and general-health-related outcomes.

**Exercise Professionals**

Exercise participation and adherence during and following cancer treatments are increased if physicians are involved in making recommendations and referring patients. Referral to a qualified exercise specialist is preferred. Minimum qualifications include a bachelor’s degree or higher in an accredited exercise science or kinesiology program. Certification as a Cancer Exercise Trainer from the American College of Sports Medicine (ACSM) further ensures that the exercise professional has the minimum competencies required to safely and effectively prescribe exercise for cancer patients and survivors. This certification, which can be obtained by individuals with varied educational backgrounds (e.g., exercise physiologists, physical therapists, nurses), requires training in the unique cancer-specific issues that need to be addressed when a patient or survivor plans to start or continue exercise throughout primary treatment and into long-term survivorship. The certification also provides a very useful professional competency benchmark for oncology professionals who are looking for exercise referral options in their local communities.

**Exercise Prescription Guidelines**

Since cancer survivors are a heterogeneous group, their exercise prescription should be individualized and tailored based on health status, disease trajectory, previous and/or current treatment, current fitness level and past and present exercise participation and preferences in order to be safe and effective. Introducing a low to moderate intensity exercise intervention and slowly increasing its frequency, intensity and duration over a period of weeks is recommended. In 2010, the...
Supportive Oncology

ACSM published the "Exercise Guidelines for Cancer Survivors," a set of evidence-based guidelines developed by a team of expert exercise oncology researchers and clinicians (see Table 2). These guidelines along with the ACSM Guidelines for Exercise Testing and Prescription provide an excellent starting point for exercise testing, prescription, and monitoring among cancer patients and survivors. The ACSM Guidelines for Cancer Survivors recommend that cancer patients and survivors slowly progress up to participating in 150 minutes of moderate intensity or 75 minutes of vigorous intensity aerobic exercise weekly plus strength training across all the major muscle groups 2 to 3 times weekly and regular stretching. The guidelines also suggest that individuals with conditions that limit their ability to perform exercise should participate in physical activity to the fullest extent they are able, even if they are unable to achieve the recommended levels.

Results from clinical trials that focus on the use of exercise for improving cancer-related outcomes are also helpful to health professionals when testing, prescribing, and monitoring exercise behavior and results. Research suggests that moderately intense exercise interventions (55–75 % of heart rate maximum, corresponding to a rating of perceived exertion between 11 and 14), including aerobic exercise ranging from 10–90 minutes in duration, 3–7 days/week, are consistently effective for managing side effects and improving QOL among cancer survivors with an early-stage diagnosis. Cancer survivors with ataxia or balance difficulties may benefit most from stationary cycling as a mode of physical exercise. Accumulating 30 minutes of daily activity through short bouts of exercise (3–10 minutes), with rest in between, can also reduce side effects and improve QOL. Moderate to vigorously intense resistance exercise performed three times per week and progressively increasing up to 2–4 sets ranging from 8–15 repetitions is effective at reducing side effects and improving QOL among cancer survivors.

Mindfulness-based modes of exercise, such as yoga and Tai Chi Chuan, performed 1–3 times a week for 60–90 minutes at a moderate intensity level can also reduce side effects and improve QOL.

Low intensity exercise is also safe and well-tolerated by cancer patients with metastatic disease. Lymphedema risk can be reduced by use of compression sleeves when appropriate, although recent research suggests that resistance training does not result in increased incidence of lymphedema. Generally, it is prudent to advise cancer patients and survivors to avoid excessive high-intensity exercise, which can compromise the immune system and interfere with treatment and recovery.

Summary

The exercise oncology literature provides consistent support for the safety and efficacy of exercise interventions in managing cancer- and treatment-related side effects as well as improving QOL in cancer patients and survivors. This area of research, however, is still in its infancy, and limitations do exist. Small sample sizes, a lack of consistency in the type and dose of exercise utilized, and methodological concerns make it difficult to generalize published findings to the diverse cancer population. Additionally, comparisons based on the dose and mode of exercise are challenging due to a lack of appropriate statistical and follow-up analyses (e.g., intent-to-treat analyses in randomized controlled trials). Despite these limitations, preliminary evidence consistently indicates that physical activity is not only safe but beneficial for cancer patients and survivors for the management of multiple side effects associated with cancer and cancer treatments. Overall, research suggests that aerobic exercise, resistance training, a combination of both, and mindfulness forms of exercise, such as yoga and Tai Chi Chuan are effective in helping cancer patients cope with their disease, improve recovery, and increase overall QOL.

Exercising Recommendations for Cancer-Related Side Effects—a Review
